- ▶ Sadinle (2014)

Duplicate detection

Duplicate detection is the task of finding sets of records that refer to the same entities within a data file.

Overview of Bayesian Fellegi and Sunter

Give an overview of the framework

Notation

Assume there are a total of n records in a database.

Assume there is one database with r records labeled

$$\{1, 2, \dots, r\}$$

where more than one record can refer to the same entity.

Assume that $n \leq r$.

Thus, we can view this problem as partitioning the database into n groups of matches/non-matches.

Representation of partitions

A partition of a set is a collection of nonempty and non-overlapping subsets whose union is the original set.

Sadinle (2014) refers such subsets **groups** or **cells**.

Example

Suppose the database has five records total $\{1, 2, 3, 4, 5\}$.

One potential partition can be represented by the following three groups:

$$\{1, 3\}, \{2\}, \{4, 5\}.$$

Each group represents an underlying entity.

In this example, records 1,3 are co-referent; records 4,5 are co-referent, and record 2 is a singleton record.

Co-reference matrix

A partition can also be represented by a matrix.

Consider the matrix Δ of dimension $r \times r$,

where

$$\Delta_{ij} = \begin{cases} 1, & \text{if records } i,j \text{ are co-referent} \\ 0, & \text{otherwise.} \end{cases}$$

Δ is referred to as the co-reference matrix.

Δ is symmetric with only ones in the diagonal.

Labellings of the partition's groups

Unfortunately, it is not computationally inefficient to utilize the co-reference matrix in practice.

An alternative is to use arbitrary labelings of the **partition's groups**.

Labellings of the partition's groups

Assume that r the maximum number of entities possibly represented in the database.

Define

$$Z_i = q, \quad i = 1, \dots, r$$

if record i represents entity q , $1 \leq q \leq r$.

$$Z = (Z_1, Z_2, \dots, Z_r)$$

contains all the records labels.

Thus,

$$\Delta_{ij} = I(Z_i = Z_j).$$

Example (Continued)

Recall our database has $\{1, 2, 3, 4, 5\}$ records and the partition can be represented by the three groups:

$$\{1, 3\}, \{2\}, \{4, 5\}.$$

What would be examples Z of arbitrary labellings for this example?

Example (Continued)

The labelings

$$Z = (1, 2, 1, 3, 3)$$

or

$$Z = (4, 1, 4, 2, 2)$$

would correspond to this partition because both $Z_1 = Z_3 = Z_4 = Z_5$ and Z_2 gets its own value.

Connection to the r th Bell number

The number of ways in which a data file with r records can be partitioned is given by the r th Bell number, which grows rapidly with r .

See Rota (1964).

Comparison data

- ▶ Comparison data are obtained by comparing pairs of records, with the goal of finding evidence of whether two records refer to the same entity.
- ▶ Intuitively, two records referring to the same entity should be very similar.

Notation

Assume f features.

Compare features f of records (i, j) by computing some similarity measure $S_f(i, j)$.

The range of $S_f(i, j)$ is divided into $L_f + 1$ intervals

$$l_{f0}, l_{f1}, \dots, l_{fL_f},$$

which represent levels of disagreement.

By convention, l_{f0} denotes the **highest level of agreement** and l_{fL_f} denotes the **lowest level of agreement**.

Notation

For records (i, j) define

$$\gamma_{ij}^f = \ell \quad \text{if} \quad S_f(i, j) \in I_{f\ell}.$$

- ▶ The larger the value of γ_{ij}^f the large the disagreement between records (i, j) with respect to feature f .
- ▶ These feature comparisons are collected into a vector for each record pair denoted by

$$\gamma_{ij} = (\gamma_{ij}^1, \gamma_{ij}^2, \dots, \gamma_{ij}^F),$$

which denotes the comparison vector for records (i, j) , where F is the number of features being compared.

Model for the Comparison Data

Assume that the comparison vector γ_{ij} is a realization of a random vector $\mathbf{\Gamma}_{ij}$.

The set of record pairs is composed of two types – co-referent and non co-referent record pairs.

Model for the Comparison Data

One expects the distribution of the comparison vectors Γ_{ij} of co-referent/non co-referent record pairs to be quite different.

For example, one expects to observe more agreements among co-referent pairs than among non-coreferent pairs.

Similarly, one expects many more disagreements among non-coreferent pairs than among co-referent pairs.

Model for the Comparison Data

This intuition can be formalized by assuming that the distribution of Γ_{ij} is the same for all record pairs that refer to the same entity and is the same for all record pairs that refer to different entities.

This is modeled as follows:

$$\Gamma_{ij} \mid \Delta_{ij} = 1 \stackrel{iid}{\sim} G_1 \quad (1)$$

$$\Gamma_{ij} \mid \Delta_{ij} = 0 \stackrel{iid}{\sim} G_0 \quad (2)$$

for all $i, j \in P$, where G_1, G_0 represent the models of the comparison vectors for pairs that are coreferent and noncoreferent, respectively.

Prior distribution on the coreference partition

The co-reference matrix represents a partition of the entries of Δ .

Let D represent the set of possible co-reference partitions.

The author assumes a uniform prior that assigns equal probability to each partition in D .

This can be written as

$$\pi(\Delta) \propto I(\Delta \in D).$$

Prior distribution on the coreference partition

One simple way to obtain this prior for Z is to assign equal probability to each of the $r!/(r - n)!$ labelings of a partition with n cells/groups.

This leads to the prior

$$p(\mathbf{Z}) \propto \frac{(r - n(\mathbf{Z}))}{r!} I(\mathbf{Z} \in Z)$$

where $n(\mathbf{Z})$ measure the number of different labelings of \mathbf{Z} .

A model for independent comparison fields

We describe a simple parametrization for G_1 and G_0 .

This model assumes that the comparison fields are independent for both co-referent and non co-referent records.

Assuming that Γ_{ij}^f takes $L_f + 1$ values corresponding to levels disagreement, one can model

$$\Gamma_{ij}^f \mid \mathbf{m}_f \sim \text{Multinomial}(\mathbf{m}_f),$$

where

$$\mathbf{m}_f = (m_{f0}, m_{f1}, \dots, m_{f,L_f-1}).$$

A model for independent comparison fields

Similarly,

$$\Gamma_{ij}^f \mid \mathbf{u}_f \sim \text{Multinomial}(\mathbf{u}_f),$$

where

$$\mathbf{u}_f = (u_{f0}, u_{f1}, \dots, u_{f,L_f-1}).$$

A model for independent comparison fields

Following the notation of Sadinle (2014),

$\Phi_0 = (u_1, \dots, u_F)$ and $\Phi_1 = (m_1, \dots, m_F)$ such that

$\Phi_f = (m_f, u_f)$.

Prior specification for the model parameters

Sadinle (2014) specified that

$$m_{f\ell} \sim \text{TruncatedBeta}(\alpha_{f\ell}^1, \beta_{f\ell}^1, \lambda_{f\ell}, 1)$$

for $\ell = 2, \dots, L_f - 1$.

In addition,

$$m_{f0} \sim \text{Beta}(\alpha_{f0}^1, \beta_{f0}^1).$$

Prior specification for the model parameters

Sadinle (2014) specified that

$$u_{f\ell} \sim \text{Uniform}(0, 1)$$

for all features and disagreement.

The author stated that one might take

$$u_{f\ell} \sim \text{Beta}(\alpha_{f0}^0, \beta_{f0}^0)$$

if prior information is available.

Gibbs sampling

In order to approximate the joint posterior of \mathbf{Z} and Φ , one must use a Gibbs sampler.

sadinle14 package

- ▶ Marchant et. al (2020) have provided a package for implementing Sadinle (2014).
- ▶ We investigate it on the RLdata500 data set.

sadinle14 package

```
library(sadinle14)
library(exchangeableER)
library(magrittr)
library(clevr)
RLdata500[['rec_id']] <- seq.int(length.out=nrow(RLdata500))
head(RLdata500)
```

| ## | fname_c1 | fname_c2 | lname_c1 | lname_c2 | by | bm | bd | rec_id |
|------|----------|----------|----------|----------|------|----|----|--------|
| ## 1 | CARSTEN | <NA> | MEIER | <NA> | 1949 | 7 | 22 | 1 |
| ## 2 | GERD | <NA> | BAUER | <NA> | 1968 | 7 | 27 | 2 |
| ## 3 | ROBERT | <NA> | HARTMANN | <NA> | 1930 | 4 | 30 | 3 |
| ## 4 | STEFAN | <NA> | WOLFF | <NA> | 1957 | 9 | 2 | 4 |
| ## 5 | RALF | <NA> | KRUEGER | <NA> | 1966 | 1 | 13 | 5 |
| ## 6 | JUERGEN | <NA> | FRANKE | <NA> | 1929 | 7 | 4 | 6 |

distance functions

```
scoringFns <- list(  
  fname_c1 = function(x, y) dist_NormLevenshtein(x, y, return.matrix = FALSE)  
  lname_c1 = function(x, y) dist_NormLevenshtein(x, y, return.matrix = FALSE)  
  by = function(x, y) dist_AbsoluteDifference(x, y, return.matrix = FALSE)  
  bm = function(x, y) dist_AbsoluteDifference(x, y, return.matrix = FALSE)  
  bd = function(x, y) dist_AbsoluteDifference(x, y, return.matrix = FALSE)  
)
```

breaks

For each scoring function above, we provide a breaks vectors which specifies the discrete levels of agreement (from 'high' agreement to 'low').

```
scoringBreaks <- list(  
  fname_c1 = c(-Inf, .05, .15, .3, Inf),  
  lname_c1 = c(-Inf, .05, .15, .3, Inf),  
  by = c(-Inf, 0, 1, 3, Inf),  
  bm = c(-Inf, 0, 1, 3, Inf),  
  bd = c(-Inf, 0, 2, 7, Inf)  
)
```

comparison vectors

- ▶ Now we are ready to compute the attribute comparison scores for the record pairs.
- ▶ Since this is a small data set, we consider all pairs using the `computePairs_all` function.
- ▶ For larger data sets, blocking/indexing is recommended using `computePairs_Hamming` or `computePairs_AttrDist`.

comparison vectors

```
pairs <- RLdata500 %>%  
  computePairs_all(id.col = 'rec_id') %>%  
  computeScores(scoringFns) %>%  
  discretizeScores(scoringBreaks)
```

speeding up inference

- ▶ To speed up inference, we only consider a subset of the pairs as candidate matches.
- ▶ Specifically, we consider pairs that have a strong agreement on name (accounting for missing names).

speeding up inference

```
pairs[['candidate']] <-  
  (pairs$fname_c1 < 4) &  
  (pairs$lname_c1 < 4) |  
  is.na(pairs$fname_c1) |  
  is.na(pairs$lname_c1)
```

priors on m and u probabilities

- ▶ Next we specify the priors on the m^* and u^* probabilities for each attribute and agreement level.
- ▶ `lambda` contains the lower truncation points for the truncated Beta priors on the m^* probabilities. `alpha1` and `beta1` are the shape parameters for the truncated Beta distributions.
- ▶ For simplicity, we specify a flat (uniform) prior. Note: the priors on the u^* probabilities are uniform by default.

priors on m and u probabilities

```
lambda <- list(  
  fname_c1 = c(0.8,0.85,0.99),  
  lname_c1 = c(0.8,0.85,0.99),  
  by = c(0.8,0.85,0.99),  
  bm = c(0.8,0.85,0.99),  
  bd = c(0.8,0.85,0.99)  
)  
  
alpha1 <- lapply(lambda, function(x) rep(1, length(x)))  
beta1 <- alpha1
```

initialization and Gibbs sampler

Finally we initialize the model and run inference using Markov chain Monte Carlo.

```
model <- sadinle14::initializeModel(pairs,
                                   lambda, alpha1,
                                   beta1, id.cols
                                   = c("rec_id.x", "rec_id.y"),
                                   candidate.col = "candidate")

result <- sadinle14::runInference(model,
                                  100, thinningInterval=10,
                                  burninInterval=100)
```

posterior samples of linkage structure

The posterior samples of the linkage structure (deduplication) are accessible from `result@history$linkage`.

However the linkage structure only includes the record in pairs.

We can obtain samples of the complete linkage structure (for all record) using the following function.

```
linkageChain <- sadinle14::completeLinkageChain(result,  
  RLdata500$rec_id)
```

evaluations

- ▶ We evaluate the quality of the posterior linkage structure (deduplication) based on a point estimate computed using the *shared most probable maximal matching sets method* from Steorts, Hall, Fienberg (2016).
- ▶ This functionality is available from the `exchangeableER` package.

```
#mpc <- exchangeableER::mostProbableClusters(linkageChain)
#predClusters <- exchangeableER::sharedMostProbableClusters
#predMatches <- exchangeableER::clustersToPairs(predClusters)
#trueClusters <- exchangeableER::membershipToClusters(identity)
#trueMatches <- exchangeableER::clustersToPairs(trueClusters)
```
